HYBRID BALANCED TASK CLUSTERING ALGORITHM FOR SCIENTIFIC WORKFLOWS IN CLOUD COMPUTING

AVINASH KAUR ∗, POOJA GUPTA † AND MANPREET SINGH ‡

Abstract. Scientific Workflow is a composition of both coarse-grained and fine-grained computational tasks displaying varying execution requirements. Large-scale data transfer is involved in scientific workflows, so efficient techniques are required to reduce the makespan of the workflow. Task clustering is an efficient technique used in such a scenario that involves combining multiple tasks with shorter execution time into a single cluster to be executed on a resource. This leads to a reduction of scheduling overheads in scientific workflows and thus improvement of performance. However, available task clustering methods involve clustering the tasks horizontally without the consideration of the structure of tasks in a workflow. We propose hybrid balanced task clustering algorithm that uses the parameter of impact factor of workflows along with the structure of workflow. According to this technique, tasks can be considered for clustering either vertically or horizontally based on the value of the impact factor. This minimizes the system overheads and the makespan for execution of a workflow. A simulation based evaluation is performed on real workflows that shows the proposed algorithm is efficient in recommending clusters. It shows improvement of 5-10% in makespan time of workflow depending on the type of workflow used.

1. Introduction. In past years of scientific discovery [16], the computational workflow continues to be popular among various disciplines of science, including astronomy [36], physics [11], biology [23, 33], seismology [25], chemistry [45] and others.

A workflow is a series of activities representing business processes or computational science with existing dependencies between them. These dependencies need to be satisfied for the achievement of a goal. Business workflow is a control-flow driven activity including constructs for specifying conditions, paths and also involve human interaction. It implements the company’s services or products. Scientific workflow involves large scale data and/or complex computations, therefore, utilizes computing resources and storage capacities [32]. It does not involve control-flow but is data-driven, while there are exceptions such as Askalon [34].

Large amount of data processing is required by scientific workflows that consist of millions of uncommon tasks [6]. For example, the Cybershake workflow [26] containing 800,000 tasks is executed on TeraGrid [41]. These loosely coupled applications in all represent a significant amount of computation and data [11]. Existing applications such as Condor [20] do not consider overheads in system, fault occurrence or restructuring of a workflow [40, 31].

To improve the scalability of the system and to reduce system overheads, workflow restructuring techniques such as task clustering is introduced [37, 18, 48]. It is a process where smaller tasks are merged into a larger job [37] that is the single execution unit in a workflow management system. After application of task clustering on tasks, the execution units are reduced and in turn, it leads to an increase in application computation, thus reducing system overheads.

However, various existing methods use trial-and-error approach for optimization of workflow structures. For example, Horizontal Clustering (HC) [37] merge different tasks at the same level of workflow horizontally. For a single task, the horizontal level is defined as the largest distance from start task of the Directed Acyclic Graph (DAG) to this task. The user controls the granularity of clustering that is the number of tasks within a cluster and defines either the number of jobs clustered per horizontal level or a number of tasks per clustered job. This kind of techniques ignored the dynamic properties of distributed environments [38].

Many methods are introduced for reducing the system overhead and clustering the tasks either horizontally or vertically but none of the technique employs both kinds of clustering simultaneously. The structure of the workflow plays a significant role in clustering of tasks of a workflow.

The work proposes hybrid balanced clustering algorithm which takes into consideration both the structure of workflow and number of jobs available for tasks to be clustered. Also, the tasks with the parent-child relationship are clustered together vertically and tasks without the relationship are considered horizontally. Hence, this helps in reducing systems overheads and faster execution of tasks and minimum wastage of resources. The important points considered in proposed work are

- Minimum tasks overheads: The overheads are reduced to the minimum while the tasks with a single parent-child relationship are clustered into one cluster. Hence, the dependency time of tasks reduces to a significant level.
- Minimum resource wastage: Algorithm ensures that the dependent tasks are provided with the data required as early as possible in order to avoid increase in waiting time and wastage of resources.

The rest of the paper is organized in the following way. The overview of related work is outlined in Section 2. Section 3 describes the workflow management system where the clustering techniques are applied. Section 4 describes the proposed algorithm. Section 5 reports the performance evaluation results of proposed technique along with available basic clustering techniques. Section 5 ends the manuscript with conclusion and future scope.

2. Literature Review.

2.1. Load imbalance. Load balancing is a topic of significance in the area of distributed computing. To balance the computational load dynamically among different resources, transfer of some jobs is required from one resource to another in a period of time. This is called task reallocation [42]. A reallocation algorithm is proposed for tuning the parallel jobs submitted to the resource manager [42]. The batch scheduler sends submission and cancellation requests. The reallocation algorithm in a multi-cluster environment is presented. To dynamically migrate processes from overloaded computational nodes to less loaded nodes a preemptive process migration method is proposed in [47]. However, it exhibits the limitation to maintain balance only with some idle nodes. In our case, we consider more tasks then available compute resources. To handle load imbalance, [15] presented techniques split tasks dynamically and consolidate them to fill idle compute nodes. Similarly, Ying et al. [46] present a load balancing algorithm based on collaborative task clustering. Level based autonomic Workflow-and-Platform Aware(WPA) task clustering technique [35] is proposed that considers the factors of workflow structure and underlying resource set size for task clustering. It aims to reduce the overhead in systems and wastage of resources.

In comparison to the techniques discussed above, our work merges the tasks based on their runtime distribution also considering the data dependencies. The overheads in our work are not introduced during runtime. Also, an approach to dynamically select the order of clustering whether vertical or horizontal is proposed.

2.2. Granularity. In scientific workflows, the techniques to control the granularity of tasks is also addressed. A label-based and level-based clustering approach is proposed by Singh et al. [37]. According to level-based clustering, considering the same horizontal level tasks are clustered. In it user specifies the number of tasks to be considered in a single cluster. In another approach of label-based clustering, the labeling of tasks is accomplished manually by the user. This method is more prone to error due to manual interaction. A task grouping and ungrouping algorithm are proposed, where information of application and resources is not known in advance [13]. Their work does not consider data dependencies but reduces queuing and scheduling overhead. An algorithm is proposed by Muthuvelu et al. [29] that group tasks based on their runtime to a resource capacity. Then, they proposed a technique [28] to determine the granularity of task based on CPU time, resource constraints and task file size. An online scheduling algorithm [27, 30] that cluster tasks based on application deadline, user’s budget and resource network utilization was introduced. Ang et al.[2] and Ng et al.[21] aimed to increase the performance in the scheduling of tasks by introducing a factor of bandwidth. Further, Liu and Liao [24] proposed a technique for executing fine-grained jobs by grouping tasks considering the processing capacity of available resources and bandwidth. An approach for reusing and repurposing workflow is presented. It uses the metric of semantic similarity between layer hierarchies of a workflow. It adopted a graph skeleton based clustering technique for grouping layer hierarchies into clusters. This technique ranked the clusters. The similarity computation used is dependent on syntactic variations [49].

As there is a large number of processes involved in the execution of a scientific workflow. This may lead to
high level of failures. A general task failure model is proposed that uses maximum likelihood based estimation for improving the execution time performance of scientific workflows [7]. This framework fails to take advantage of the combination of horizontal and vertical clustering.

2.3. Structural similarity. In [22] SFLA technique is proposed for encoding of workflows through workflow representations by exploiting set descriptors. In [50] author proposes a method for reusing and repurposing of a workflow by calculating the semantic similarity between layers of different workflows. These hierarchies are grouped into clusters. The author proposed a SimiFlow architecture for supporting clustering of workflows based on similarity.

2.4. Data dependency. Although the proposed techniques significantly decrease the impact of queuing time overhead and scheduling, they did not consider the factor of data dependencies. As clustering, the tasks horizontally increases the problem of dependency imbalance and runtime imbalance. To overcome these problems, three new methods of clustering Horizontal Runtime balancing, Horizontal impact factor balancing and Horizontal Distance Balancing are proposed in [10]. In these algorithms, only horizontal clustering is performed. In a workflow, there can be tasks with single parent single child relationship. In these kinds of tasks, vertical clustering can prove to be more advantageous than horizontal clustering technique. A general task failure model is proposed that uses maximum likelihood based estimation for improving the execution time performance of scientific workflows [7]. This framework fails to take advantage of the combination of horizontal and vertical clustering considering the single parent and child relationship in the nodes of a workflow. The deciding factor is unexplainable in research so as to choose whether to cluster tasks vertically or horizontally so as to maintain parallelism.

The existing work suffers from one or the following drawbacks

• The data dependencies between tasks not considered
• The runtime imbalance and dependency imbalance not considered
• The structure of workflow not considered
• The maximum parallelism between tasks not exploited

This work proposes Hybrid balanced task clustering technique to perform clustering while maintaining the parallelism of the system considering the single parent single child relationships in the nodes of workflow. Hybridizations of horizontal and vertical clustering technique has been achieved using impact factor based clustering technique. The cluster size is dynamically set as per job runtime to maintain the parallelism. Dependency variance is calculated using distance metrics. Horizontal and vertical clustering is performed as per the available resources, so that the parallelism is not affected. Hybrid clustering improves the performance of scientific workflow in cloud computing and a further benefit to data placement.

3.1. Workflow. The Workflow Management Coalition (WFMC) defined a workflow as the automation of a business process, in whole or part, during which documents, information or tasks are passed from one participant to another for action, according to a set of procedural rules [17]. By the definition given by WFMC, the work process is a progression of organized exercises and calculations of a business procedure which is a unique depiction of the undertakings to be executed in that business process. They are utilized to join a few diverse computational procedures into a solitary lucid procedure. The business applications can now be seen as perplexing work processes, which comprise of different changes performed on the information fancied in accomplishing the goal. Workflows offer awesome points of interest in isolating capacities from applications and in this manner offering data framework to be segmented based by first arranging them and then incorporating them.

WFMC introduces its reference model in recognizing the interfaces inside of this structure which empowers items to operate interactively at an assortment of levels. It characterizes a work management framework and the most critical interfaces of a system as in Figure 3.1.

• Workflow Engine: A software service that gives the run-time environment with a specific end term goal to make, oversee and execute work process cases.
• Process Definition: Specifies the information about the process and the workflows related to it.
3.2. Workflow model. A workflow application $Wf=(V_i, E_i)$ is represented as a directed acyclic graph (DAG) where $V_i=v_{i1}, v_{i2}..., v_{in}$ is a set of vertices representing tasks and $E_i$ represents edges control or data dependencies between them. A dependency $e_{ij}$ is the precedence constraint of the form $(v_{i1}, v_{j1})$, where $v_{i1}, v_{j1} \in V_i$ and $v_{i1} \neq v_{j1}$. This refers to that the child task can only complete its execution if the parent task has completed the execution. An example workflow is shown in Figure 3.2.

3.3. Workflow execution environment. A workflow is submitted to a workflow management system for execution that resides on a submit hosts which is user interaction machine. The execution machine for a workflow can be a grid, physical cluster [12], a dedicated parallel system [26], a virtual environment such as the cloud [4] or it can also be a local machine. Figure 3.3 shows a typical execution environment for scientific workflows. The components of this environment are listed below:

**Workflow Mapper** responsible for the generation of an executable workflow on the basis of an abstract workflow as submitted by a composition system or a user of the workflow. It finds the appropriate computational resources and data required for execution of a workflow. For optimization of performance, Workflow Mapper also restructures the workflow and add transformation for provenance information generation and data management.

**Workflow Engine** is responsible for the execution of jobs as per dependencies defined by the workflow. It manages the jobs by tracking their status. The jobs whose parent jobs have completed are given to the Job Scheduler.
4. Hybrid Balanced Task Clustering algorithm. In this, the proposed hybrid balanced clustering algorithm used for task clustering is discussed which is not dependent on the input of the user. It is able to cluster the tasks vertically with single parent single child relationship and the tasks horizontally as well. The system overhead is reduced while involving best utilization of resources. The flowchart of proposed technique is depicted in Figure 4.1. The symbols used in this work are explained in Table 3.1.

4.1. Background. The two major issues that are undertaken by the clustering algorithms, dependency imbalance, and runtime imbalance. Runtime imbalance refers to the unequal distribution of runtime of tasks at

the same horizontal level. While dependency imbalance refers to clustering tasks at a level without considering the factor of dependency between tasks. This increases the waiting time for input at the next level and thus the delay in execution. The problem is also referred to as data locality. Generally, runtime imbalance leads to dependency imbalance and dependency imbalance leads to runtime imbalance. The structure of workflow is also an important factor while clustering the tasks. As horizontal clustering is always performed for tasks that may increase the problems of runtime imbalance and dependency imbalance. So instead of performing task clustering horizontally at each level of workflow, vertical clustering can also be performed of the tasks where single parent single child relationship exists between tasks besides performing clustering horizontally. This may lead to improvement in the execution of workflow while further decreasing the delays. Considering the above challenges of clustering, the introduced method aims to obtain appropriate hybrid clustering while merging the tasks vertically with the similar impact factor and remaining tasks horizontally according to number of available resources. Thus reducing the overall execution time. For the realization of the desired clustering, the proposed Hybrid balancing algorithm as follows.

Algorithm working: This technique prefers to cluster the tasks with single parent single child relationship. The problem of dependency imbalance is catered by measuring the impact factor of tasks in the workflow. The Impact Factor (IF) of task \( t_n \) is denoted by

\[
IF(t_n) = \sum_{t_a \in \text{child}(t_n)} \frac{IF(t_a)}{\text{parent}(t_a)}
\]

where \( \text{child}(t_a) \) denotes a set of child tasks of \( t_a \) and \( \text{parent}(t_a) \) denotes set of parent tasks of \( t_a \). The impact factor is used to measure the similarity between the tasks or jobs[9].

The proposed algorithm ensures that the tasks with one parent-child relationship are clustered into one cluster. The remaining tasks are then clustered horizontally. The parent child relationship is depicted by matching the impact factor of tasks vertically. The tasks with the similar impact factor are grouped into one cluster. This help in reducing the execution time of workflow. For example figure 4.2 shows a five-level workflow composed of one task at level one, two tasks at level-two, four tasks at level-three, three tasks at level-four and one task at level-five.

Algorithm 1 shows the pseudo code of hybrid balancing algorithm that uses the combination of horizontal distance balancing [10], horizontal runtime balancing [10] and impact factor [10] of tasks. We assume the number of jobs as an input from the user. This algorithm addresses the problem of load imbalance and also considers the tasks with asymmetric structure. The algorithm begins with the first level of workflow as in Figure 4.2 by selecting tasks from each level (Lines 2-3). Tasks are clustered into a job and returned by merge procedure (Line 4). The merge procedure merges the tasks vertically and horizontally also. In merge procedure, the tasks are sorted according to decreasing order of runtime (Line 13). Considering the level three of a workflow. There are four tasks D(30s),E(10s),F(30s),G(20s). The task list LT is maintained as according to decreasing order
of runtime of tasks $LT = D, F, G, E$. Then horizontal runtime balancing adds the task $D$ to the job with the shortest runtime as in Figure 4.3.

**Step 2:** The tasks are arranged as per the minimum distance with the task $D$. $Distance = 0(D), 4(F), 4(G), 2(E)$. The impact factor of task $D$ included in a job is matched vertically to depict parent-child relationship exists or not. If the relationship exists then the child task is added to the job where task $D$ resides (Lines 20-22) as shown in Figure 4.4 and Figure 4.5.

**Step 3:** Now after the clustering of tasks $D$ and $H$. The tasks in a task list ($LT$) are task $F, G, E$. The horizontal distance balancing is performed on tasks $E, F$ and $G$. In this jobs $J_1, J_2, J_3$ are sorted based on shortest distance between them and targeted task $D$. The distances are $4, 4, 2$ respectively for tasks $F, G, E$. The candidate is selected with minimal distance 2 of task $E$. Hence impact factor of task $E$ is matched vertically and if the impact factor matches with the below vertically then both are clustered into another cluster $c_2$ as shown in Figure 4.6 and merged as a job $J_2$ as shown in Figure 4.7.

**Step 4:** Now the tasks left in the task list $LT$ are $F$ and $G$. Similarly the process is repeated for the tasks $F$ and $G$. But these tasks do not have a parent child relationship with any task. So they cannot be clustered vertically. Hence Horizontal clustering is performed for the tasks $F, G$ forming cluster $c_3$ as shown in Figure 4.8 and merging into job $J_3$ as shown in Figure 4.9.

5.1. Scientific workflow applications. Montage [3] is one of the application of astronomy used for constructing large image mosaics of the sky. In it, the input images are projected onto a sphere and then the overlap for each input image is calculated. The input images are projected to the accurate orientation while maintaining the constant emission level of background for all images. At last, reprojected images are added into a final mosaic. The final resulting image provides a detailed description of the part of the sky under investigation. Figure 5.1 represents the Montage workflow. The size of the workflow is dependent upon the number of images used for constructing the desired mosaic of the sky.

Cybershake. CyberShake [14] is an application of seismology that is used for calculating Probabilistic Seismic Hazard curves for various geographic regions in Southern California. It is used in the identification of all ruptures within 200KM radius. It also changes rupture into multiple variations of rupture that differ in hypocenter locations and slip distributions. Then for each rupture variance, synthetic seismograms are calculated. After that, the peak intensity is extracted and added with the original rupture probability for production probabilistic hazards for the location. Figure 5.2 shows an illustration of the Cybershake workflow.

Epigenomics. The Epigenomics workflow [44] is a CPU-intensive application. Initially the data is obtained in the form of DNA sequence lanes from the Illumina-Solexa Genetic Analyzer. Every Solexa machine generates multiple DNA sequences. Then the mapping of DNA sequences to the accurate locations in a genome is performed by the workflow. This produces a map showing the density of sequence. A simplified structure of Epigenomics is shown in Figure 5.3.

SIPHT. The SIPHT workflow [19] is responsible for researching small untranslated RNAs (sRNAs). It is responsible for regulation of different processes such as virulence or secretion in bacteria. This predict \(\rho\)-independent transcriptional terminators. A simplified version of SIPHT workflow is depicted in Figure 5.4.
In Laser Interferometer Gravitational Wave Observatory (LIGO) workflows data is collected by large-scale interferometers for searching of gravitational wave signatures. The observers aim is to measure and detect waves as predicted by relativity. It is a data-intensive workflow. Figure 5.5 depict a version of workflow. In this workflow tasks are separated into different groups where a group consisting of interconnected tasks as shown in Figure 5.5.

5.2. Balanced Task Clustering algorithms. The task clustering techniques are classified into two different categories Horizontal clustering and vertical clustering. Further to overcome the limitations of these techniques, balanced clustering is introduced.

5.3. Description of Baseline Balanced Clustering Algorithms. In order to study the impact of the proposed clustering technique, the clustering methods considered are: Horizontal Impact Factor Balancing (HIFB) Horizontal Clustering (HC), Horizontal Distance Balancing (HDB) and Horizontal Runtime balancing (HRB) [8, 10].

**Horizontal Clustering (HC):** In this technique tasks at the same horizontal level of workflow is merged into a job. The horizontal level for a single task is considered as the largest distance from the first task of workflow starting from the first task. The first task is a task without a parent task.

As shown in Figure 5.6, the tasks t2, t3 and t4 are combined together into a cluster c1, thus creating just one job j1. The horizontal clustering is performed for the tasks at the same level. Thus reducing the overhead.

**Vertical Clustering Clustering (VC):** In this algorithm task at the same vertical level of a workflow are merged and make a single job. In this, the tasks with relationship between one parent and one child are merged.

As shown in Figure 5.7 the tasks t2, t5, t8 exhibit parent-child relationship as t2 is parent of t5 and further
t5 is parent t8. So these tasks are clustered together into a cluster c1, thus creating a job1. Similarly t3, t6, t9 and t4, t7, t10 are clustered into clusters c2,c3 thus creating combined jobs job2, job3 respectively. The overheads are also combined into overheads o2, o3 and o4.

**Horizontal Runtime Balancing (HRB):** In this algorithm runtime of tasks is equally distributed between jobs. The problem of runtime variance is addressed at the same horizontal level. In this greedy method, the jobs are sorted according to the ascending order of runtime. The new task is joined to the job with a minimum runtime. This method further raises the dependency imbalance among tasks as the factor of data dependency is not considered while clustering.

As shown in Figure 5.8, there are four tasks t1, t2 and t3, t4 with runtime 20s and 30s respectively. According to this clustering method tasks t1, t3 are combined into one cluster and t2, t4 are combined into another cluster. This balances the runtime among tasks, but leads to dependency imbalance among tasks.

**Horizontal Impact Factor Balancing (HIFB):** It overcomes the limitation of Horizontal runtime balancing algorithm of dependency imbalance. In this algorithm, the jobs are first sorted by considering the similarity of impact factor (IF) in increasing order. Then the shortest job is selected using Horizontal Runtime Balancing. It groups the jobs sharing the same position in the workflow.

As shown in Figure 5.9 the tasks t1, t2 and t3, t4, t5 have same the impact factor. Then using HRB the tasks t1, t2 and t3, t4 are combined into clusters c1, c2.
Horizontal Distance Balancing (HDB): In this clustering technique jobs are sorted considering the distance between them and the target job. After that Horizontal Runtime Balancing method is executed for selecting the shortest job. The tasks with minimum distance are merged thus reducing data transfer.

As in Figure 5.10 the tasks t1 and t2 are closest as compared to distance between t1, t3 and t1, t4. So t1, t2 are combined into one cluster and t3, t4 are combined into another cluster.

The performance of above discussed algorithms has been evaluated using workflowsim on various datasets e.g. Montage, LIGO.

5.4. Experiments and Results.

Experimental setup. The trace based simulation method is adopted for evaluation. The performance of the proposed technique is compared with the baseline algorithm. Real traces are used for evaluation of algorithms. In the environment, different system parameters used are a number of virtual machines, system overhead, different workflows and sizes of data.

For executing applications of workflow, open source workflow simulator, workflowsim is used. It is used for modeling an execution environment in the cloud. It is an extension of cloudsim. The DAG model of workflow is executed in it. It performs clustering and scheduling of tasks. It also performs provisioning of resources at the workflow level.

In the experiment, the simulator WorkflowSim is extended to implement the proposed hybrid balanced task clustering technique. A virtual machine cluster consisting of 20 single homogeneous core VMs is considered. This cluster is a quota for a user in some distributed environments such as Amazon EC2. Each VM detains
Fig. 5.7. Vertical clustering.

Fig. 5.8. A sample of the HRB (Horizontal Runtime Balancing) method.

Fig. 5.9. HIFB (Horizontal Impact Factor Balancing) method.
The configuration setup for the experiment is described as in Table 5.1.

An evaluation of the proposed technique was performed for identification of its ability. The method was evaluated for the improvement in execution time of scientific workflow and reducing the load to minimum resources. The experiment is conducted on the following variables.

- **Execution time of workflow**: Total time taken by the workflow application to execute on the available resources.

- **Performance Gain ($\mu$)**: It is defined as an overall improvement in execution time of workflow by using the clustering algorithm over the execution of the workflow without clustering of a task. It can be evaluated using equation as follows:

$$\mu = \frac{(\text{time taken without clustering} - \text{time taken with clustering})}{\text{time taken without clustering}} \times 100$$

$\mu > 0$ for a clustering technique signifies that it leads to improvement of the execution time of a workflow. Whereas $\mu < 0$ refers to negative impact of clustering method. This negative impact lead to increase of execution time of workflow.

Three set of experiments are conducted on the scientific workflow applications.

**Experiment 1: Improvement in execution time** The makespan time of balanced clustering algorithms on different scientific workflow applications cybershake, epigenomics, LIGO, Montage and SIPHT is obtained from the experiments performed. The makespan time is depicted in Table 5.3. According to the experimental evaluations the following results are depicted:

- **Cybershake Workflow Application**: In this application, there is 26% and 10% improvement in execution time by hybrid balanced clustering algorithm (HYB) then horizontal impact factor balancing (HIFB) and horizontal clustering (HC) respectively.

- **Epigenomics workflow application**: In this application, there is 14.78%, 13.68%, 13.76% improvement in execution time by Hybrid Balanced Clustering algorithm then horizontal impact factor balancing (HIFB), Horizontal Distance Balancing (HDB) and Horizontal Clustering (HC) respectively.

- **LIGO**: In this application there is 23.75%, 11.77%, 10.60% and 8.87% improvement in execution time by Hybrid Balanced Clustering algorithm then Horizontal impact factor balancing (HIFB), Horizontal Clustering (HC), Horizontal Distance balancing (HDB) and Horizontal runtime balancing (HRB) respectively.

- **Montage Workflow Application**: In this application there is 23%, 2.46% improvement in execution time of workflow by Hybrid Balanced Clustering algorithm then Horizontal Clustering (HC) and Horizontal Distance Balancing respectively.

- **SIPHT**: In this application there is 58%, 55% and 48% improvement in execution time by Hybrid Balanced Clustering algorithm then Horizontal Impact Factor Balancing (HIFB), Horizontal Clustering (HC) and Horizontal Distance Balancing (HDB) respectively.

Hence from the experiment 1, it is concluded that the execution time taken by Hybrid Balanced Task Clustering algorithm (HYB) is lesser as compared to other baseline algorithms. Proposed technique shows the overall improvement in execution time.

**Experiment 2: Performance Gain** In this experiment, the performance gain (\(\mu\)) of the proposed technique is evaluated with the other clustering algorithms. In this experiment, the proposed technique is evaluated for identification of the amount to which it impacts the overall execution time of workflow. Figure 5.4 shows the performance gain \(\mu\) for different clustering methods obtained by the performed experiment. From the experiments, it is depicted that all the methods of clustering retain a positive gain performance. This further improves the execution time of different workflow applications. According to obtained results Montage, CyberShake and SIPHT workflows have better performance gains with a minimum gain of 52%, 41% and 59%. In comparison LIGO and Epigenomics having a minimum performance gain of 32% and 18% respectively. The variation in performance gain is due to the granularity of the average runtime of tasks in workflows. Considering the workflows the lowest value for the performance gain is for HIFB in SIPHT workflow. In all the scientific workflows, the technique Horizontal Runtime Balancing (HRB) and proposed Hybrid balanced Task clustering (HYB) method performs better than the other balancing techniques. The clustering method HDB (Horizontal Distance Balancing) and HIFB (Horizontal Impact Factor Balancing) lack in performance, because there runtime as well as
dependency imbalance between tasks. This groups the tasks into a cluster that should execute in parallel leading to an increase in execution time of workflow. The proposed hybrid balancing clustering method delivers a good performance since it first checks for parent-child relationship and then clusters the tasks. Thus increasing the performance gain and decreasing overall execution time of workflow as shown in Figure 5.11.

**Experiment 3: Varying virtual machines** In experiment 3, the number of virtual machines are varied while keeping the total number of tasks 1000 MIPS.

First, the experiment is performed by using a horizontal clustering technique while varying the number of virtual machines (VM) as shown in Figure 5.12.

The same experiment is conducted by using hybrid balanced clustering algorithm and the result is depicted as shown in Figure 5.13.

While comparing both the results, it is found that horizontal clustering technique performs in a similar manner inspite of more number virtual machines available. While in the proposed algorithm, the execution time decreases as the number of virtual machines increases. Hence leading to an increase in performance of execution of workflow applications. But at an instance the proposed technique performs as similar to baseline algorithms. This depicts the proposed technique also reaches a stagnation point but after more of the resource utilization in comparison to baseline algorithms.

As in Figure 5.12 the graph depicts the number of virtual machines increases the execution time decreases but at an instant the performance is constant and it does not matter on adding more virtual machines. The proposed technique is performing in a similar manner and adding up the virtual machines decreases the execution time. But at a point the performance becomes constant.

6. Conclusion and Future Scope.

The work proposes a hybrid balancing (HYB) task clustering method that reduces the full time of workflow execution and thus avoids waste of resources. The proposed approach considers distance variance and merges the tasks with similar impact factor in pipeline. A simulation experiment is conducted for evaluation of the proposed algorithm in comparison to four clustering methods: Horizontal Runtime Balancing (HRB), Horizontal Clustering (HC), Horizontal Distance Balancing (HDB), and Horizontal Impact Factor Balancing (HIFB). The experiment aimed to evaluate the execution time improvement. The results depict that the proposed clustering method is able to perform better than the other methods. Hence it can be used in different workflow structures.

In near future, it is intended that the size of the resource set can be identified for optimized execution of a workflow. Also, the proposed approach can be implemented in a workflow engine. So that this approach can be used for clustering tasks in a real environment.
